12.1 Handling exceptions using try and except

Error-checking code is code that a programmer introduces to detect and handle errors that may occur while the program executes. Python has special constructs known as ***exception-handling*** constructs because they handle *exceptional circumstances*, another word for errors during execution.

Consider the following program that has a user enter weight and height, and that outputs the corresponding body-mass index (BMI is one measure used to determine normal weight for a given height).

Figure 12.1.1: BMI example without exception handling.

```
user_input = ''
while user_input != 'q':
    weight = int(input("Enter weight
(in pounds): "))
    height = int(input("Enter height
(in inches): "))

    bmi = (float(weight) /
float(height * height)) * 703
    print('BMI:', bmi)
    print('(CDC: 18.6-24.9 normal)\n')
    # Source www.cdc.gov

    user_input = input("Enter any key
('q' to quit): ")
```

```
Enter weight (in pounds): 150
Enter height (in inches): 66
BMI: 24.207988980716255
(CDC: 18.6-24.9 normal)

Enter any key ('q' to quit): a
Enter weight (in pounds): One-hundred fifty
Traceback (most recent call last):
  File "test.py", line 3, in <module>
    weight = int(input("Enter weight (in
pounds): "))
ValueError: invalid literal for int() with base
10: 'One-hundred fifty'
```

Above, the user entered a weight by writing out "One-hundred fifty", instead of giving a number such as "150", which caused the int() function to produce an exception of type ValueError. The exception causes the program to terminate.

Commonly, a program should gracefully handle an exception and continue executing, instead of printing an error message and stopping completely. Code that potentially may produce an exception is placed in a ***try*** block. If the code in the try block causes an exception, then the code placed in a following ***except*** block is executed. Consider the program below, which modifies the BMI program to handle bad user input.

Figure 12.1.2: BMI example with exception handling using try/except.

```
user_input = ''
while user_input != 'q':
    try:
        weight = int(input("Enter weight (in
pounds): "))
        height = int(input("Enter height (in
inches): "))

        bmi = (float(weight) / float(height *
height)) * 703
        print('BMI:', bmi)
        print('(CDC: 18.6-24.9 normal)\n')  #
Source www.cdc.gov
    except:
        print('Could not calculate health
info.\n')

    user_input = input("Enter any key ('q' to
quit): ")
```

```
Enter weight (in pounds): 150
Enter height (in inches): 66
BMI: 24.207988980716255
(CDC: 18.6-24.9 normal)

Enter any key ('q' to quit): a
Enter weight (in pounds): One-
hundred fifty
Could not calculate health info.

Enter any key ('q' to quit): a
Enter weight (in pounds): 200
Enter height (in inches): 62
BMI: 36.57648283038502
(CDC: 18.6-24.9 normal)

Enter any key ('q' to quit): q
```

The try and except constructs are used together to implement ***exception handling***, meaning handling exceptional conditions (errors during execution). A programmer could add additional code to do their own exception handling, e.g., checking if every character in the user input string is a digit, but such code would make the original program difficult to read.

Construct 12.1.1: Basic exception handling constructs.

```
try:
    # ... Normal code that might produce errors
except: # Go here if any error occurs in try
block
    # ... Exception handling code
```

PARTICIPATION ACTIVITY 12.1.1: How try and except blocks handle exceptions.

Animation captions:

1. When a try is reached, the statements in the try block are executed.
2. Any statements in the try block not executed before the exception occurred are skipped.

When a try is reached, the statements in the try block are executed. If no exception occurs, the except block is skipped and the program continues. If an exception does occur, the except block is executed, and the program continues *after* the try block. Any statements in the try block not executed before the exception occurred are skipped.

PARTICIPATION ACTIVITY 12.1.2: Exception basics.

1) Execution jumps to an except block only if an error occurs in the preceding try block.
   - ○ True
   - ○ False

2) After an error occurs in a try block, and the following except block has executed, execution resumes after where the error occurred in the try block.
   - ○ True
   - ○ False

Table 12.1.1: Common exception types.

Type	Reason exception is raised
EOFError	input() hits an end-of-file condition (EOF) without reading any input
KeyError	A dictionary key is not found in the set of keys
ZeroDivisionError	Divide by zero error
ValueError	Invalid value (Ex: Input mismatch)
IndexError	Index out of bounds

Source: Python: Built-in Exceptions

12.2 Multiple exception handlers

Sometimes the code in a try block may generate different types of exceptions. In the previous BMI example, a ValueError was generated when the int() function was passed a string argument that contained letters. Other types of errors (such as NameError, TypeError, etc.) might also be generated, and thus a program may need to have unique exception handling code for each error type. Multiple ***exception handlers*** can be added to a try block by adding additional except blocks and specifying the specific type of exception that each except block handles.

Construct 12.2.1: Multiple except blocks.

```
try:
    # ... Normal code
except exceptiontype1:
    # ... Code to handle exceptiontype1
except exceptiontype2:
    # ... Code to handle exceptiontype2
...
except:
    # ... Code to handle other exception
types
```

PARTICIPATION ACTIVITY 12.2.1: Multiple exception handlers.

Animation captions:

1. Multiple exception handlers can be added to a try block by adding additional except blocks and specifying the particular type of exception that each except block handles.

An except block with no type (as in the above BMI example) handles any unspecified exception type, acting as a catch-all for all other exception types. Good practice is to generally *avoid* the use of a catch-all except clause. A programmer should instead specify the particular exceptions to be handled. Otherwise, a program bug might be hidden when the catch-all except clause handles an unexpected type of error.

If no exception handler exists for an error type, then an ***unhandled exception*** may occur. An unhandled exception causes the interpreter to print the exception that occurred and then halt.

The following program introduces a second exception handler to the BMI program, handling a case where the user enters "0" as the height, which would cause a ZeroDivisionError exception to occur when calculating the BMI.

Figure 12.2.1: BMI example with multiple exception types.

```
user_input = ''
while user_input != 'q':
    try:
        weight = int(input("Enter weight (in
pounds): "))
        height = int(input("Enter height (in
inches): "))

        bmi = (float(weight) / float(height *
height)) * 703
        print('BMI:', bmi)
        print('(CDC: 18.6-24.9 normal)\n')  #
Source www.cdc.gov
    except ValueError:
        print('Could not calculate health
info.\n')
    except ZeroDivisionError:
        print('Invalid height entered. Must be >
0.')

    user_input = input("Enter any key ('q' to
quit): ")
```

```
Enter weight (in pounds): 150
Enter height (in inches): 66
BMI: 24.207988980716255
(CDC: 18.6-24.9 normal)

Enter any key ('q' to quit): a
Enter weight (in pounds): One-
hundred fifty
Could not calculate health info.

Enter any key ('q' to quit): a
Enter weight (in pounds): 150
Enter height (in inches): 0
Invalid height entered. Must be >
0.
Enter any key ('q' to quit): q
```

In some cases, multiple exception types should be handled by the same exception handler. A tuple can be used to specify all of the exception types for which a handler's code should be executed.

Figure 12.2.2: Multiple exception types in a single exception handler.

```
try:
    # ...
except (ValueError, TypeError):
    # Exception handler for any ValueError or TypeError that
occurs.
except (NameError, AttributeError):
    # A different handler for NameError and AttributeError
exceptions.
except:
    # A different handler for any other exception type.
```

PARTICIPATION ACTIVITY 12.2.2: Multiple exceptions.

1) Fill in the missing code so that any type of error in the try block is handled.

```
ages = []
prompt = "Enter age ('q' to
quit):"
user_input = input(prompt)
while user_input != 'q':
      try:

ages.append(int(user_input))
            user_input =
input(prompt)
            except:
            print('Unable to
add age.')
print(ages)
```

Check Show answer

2) An AttributeError occurs if a function does not exist in an imported module. Fill in the missing code to handle AttributeErrors gracefully and generate an error if other types of exceptions occur.

```
import my_lib
try:
      result = my_lib.magic()
      except:
      print('No magic()
function in my_lib.')
```

Check Show answer

3) If a file cannot be opened, then an IOError may occur. Fill in the missing code so that the program specially handles AttributeErrors and IOErrors, and also doesn't crash for any other type of error.

```
import my_lib
try:
      result = my_lib.magic()
      f = open(result, 'r')
      print f.read()

      print('Could not open
file.')
except AttributeError:
      print('No magic()
function in my_lib')
```

CHALLENGE ACTIVITY 12.2.1: Enter the output of multiple exception handlers.

334598.939404.qx3zqy7

Start

Type the program's output

```
user_input = input()
while user_input != 'end':
    try:
        # Possible ValueError
        divisor = int(user_input)
        # Possible ZeroDivisionError
        print(60 // divisor) # Truncates to an integer
    except ValueError:
        print('v')
    except ZeroDivisionError:
        print('z')
    user_input = input()
print('OK')
```

12.3 Raising exceptions

Consider the BMI example once again, in which a user enters a weight and height, and that outputs the corresponding body-mass index. The programmer may wish to ensure that a user enters only valid heights and weights, i.e., greater than 0. Thus, the programmer must introduce error-checking code.

A naive approach to adding error-checking code is to intersperse if-else statements throughout the normal code. Of particular concern is the yellow-highlighted code, which is new branching logic added to the normal code, making the normal code flow of "get weight, get height, then print BMI" harder to see. Furthermore, the second check for negative values before printing the BMI is redundant and ripe for a programming error caused by inconsistency with the earlier checks (e.g., checking for <= here rather than just <).

Figure 12.3.1: BMI example with error-checking code but without using exception-handling constructs.

```
user_input = ''
while user_input != 'q':
    weight = int(input('Enter weight (in pounds): '))
    if weight < 0:
        print('Invalid weight.')
    else:
        height = int(input('Enter height (in inches): '))
        if height <= 0:
            print('Invalid height')

    if (weight < 0) or (height <= 0):
        print('Cannot compute info.')
    else:
        bmi = (float(weight) / float(height * height)) * 703
        print('BMI:', bmi)
        print('(CDC: 18.6-24.9 normal)\n')  # Source
www.cdc.gov

    user_input = input("Enter any key ('q' to quit): ")
```

The following program shows the same error-checking carried out using exception-handling constructs. The normal code is enclosed in a try block. Code that detects an error can execute a ***raise*** statement, which causes immediate exit from the try block and the execution of an exception

handler. The exception handler prints the argument passed by the raise statement that brought execution there. The key thing to notice is that the normal code flow is not obscured via new if-else statements. You can clearly see that the flow is "get weight, get height, then print BMI".

Figure 12.3.2: BMI example with error-checking code that raises exceptions.

```
user_input = ''
while user_input != 'q':
    try:
        weight = int(input('Enter weight (in pounds):
'))
        if weight < 0:
            raise ValueError('Invalid weight.')

        height = int(input('Enter height (in inches):
'))
        if height <= 0:
            raise ValueError('Invalid height.')

        bmi = (float(weight) * 703) / (float(height *
height))
        print('BMI:', bmi)
        print('(CDC: 18.6-24.9 normal)\n')
        # Source www.cdc.gov

    except ValueError as excpt:
        print(excpt)
        print('Could not calculate health info.\n')

    user_input = input("Enter any key ('q' to quit): ")
```

```
Enter weight (in pounds): 166
Enter height (in inches): 55
BMI: 38.57785123966942
(CDC: 18.6-24.9 normal)

Enter any key ('q' to quit): a
Enter weight (in pounds): 180
Enter height (in inches): -5
Invalid height.
Could not calculate health
info.

Enter any key ('q' to quit): a
Enter weight (in pounds): -2
Invalid weight.
Could not calculate health
info.

Enter any key ('q' to quit): q
```

A statement like `raise ValueError('Invalid weight.')` creates a new exception of type ValueError with a string argument that details the issue. The programmer could have specified any type of exception in place of ValueError, e.g., NameError or TypeError, but ValueError most closely describes the exception being handled in this case. The ***as*** keyword binds a name to the exception being handled. The statement `except ValueError as excpt` creates a new variable excpt that the exception handling code might inspect for details about the exception instance. Printing the variable excpt prints the string argument passed to the exception when raised.

12.4 Exceptions with functions

The power of exceptions becomes even more clear when used within functions. If an exception is raised within a function and is not handled within that function, then the function is immediately exited and the calling function is checked for a handler, and so on up the function call hierarchy. The following program illustrates. Note the clarity of the normal code, which obviously "gets the weight, gets the height, and prints the BMI" – the error checking code does not obscure the normal code.

Figure 12.4.1: BMI example using exception-handling constructs along with functions.

```
def get_weight():
    weight = int(input('Enter weight (in pounds): '))
    if weight < 0:
        raise ValueError('Invalid weight.')
    return weight

def get_height():
    height = int(input('Enter height (in inches): '))
    if height <= 0:
        raise ValueError('Invalid height.')
    return height

user_input = ''
while user_input != 'q':
    try:
        weight = get_weight()
        height = get_height()

        bmi = (float(weight) / float(height * height)) *
703
        print('BMI:', bmi)
        print('(CDC: 18.6-24.9 normal)\n')
        # Source www.cdc.gov

    except ValueError as excpt:
        print(excpt)
        print('Could not calculate health info.\n')

    user_input = input("Enter any key ('q' to quit): ")
```

```
Enter weight (in pounds): 150
Enter height (in inches): 66
BMI: 24.207988980716255
(CDC: 18.6-24.9 normal)

Enter any key ('q' to quit): a
Enter weight (in pounds): -1
Invalid weight.
Could not calculate health
info.

Enter any key ('q' to quit): a
Enter weight (in pounds): 150
Enter height (in inches): -1
Invalid height.
Could not calculate health
info.

Enter any key ('q' to quit): q
```

Suppose get_weight() raises an exception of type ValueError. The get_weight() function does not handle exceptions (there is no try block in the function) so it immediately exits. Going up the

function call hierarchy returns execution to the global scope script code, where the call to get_weight() was in a try block, so the exception handler for ValueError is executed.

Notice the clarity of the script's code. Without exceptions, the get_weight() function would have had to somehow indicate failure, perhaps through a special return value like -1. The script would have had to check for such failure and would have required additional if-else statements, obscuring the functionality of the code.

PARTICIPATION ACTIVITY 12.4.1: Exceptions in functions.

1) For a function that may contain a raise statement, the function's statements must be placed in a try block within the function.
   - ○ True
   - ○ False

2) A raise statement executed in a function automatically causes a jump to the last return statement found in the function.
   - ○ True
   - ○ False

3) A key goal of exception handling is to avoid polluting normal code with distracting error-handling code.
   - ○ True
   - ○ False

12.5 Using finally to cleanup

Commonly a programmer wants to execute code regardless of whether or not an exception has been raised in a try block. For example, consider if an exception occurs while reading data from a file – the file should still be closed using the file.close() method, no matter if an exception interrupted the read operation. The ***finally*** clause of a try statement allows a programmer to specify *clean-up* actions that are always executed. The following illustration demonstrates.

PARTICIPATION ACTIVITY 12.5.1: Clean-up actions in a finally clause are always executed.

Animation captions:

1. If no exception occurs, then execution continues in the finally clause and then proceeds with the rest of the program.
2. If a handled exception occurs, then an exception handler executes and then the finally clause executes.

The finally clause is always the last code executed before the try block finishes.

- If *no exception* occurs, then execution continues in the finally clause, and then proceeds with the rest of the program.
- If a *handled exception* occurs, then an exception handler executes and then the finally clause.
- If an *unhandled exception* occurs, then the finally clause executes and then the exception is re-raised.
- The finally clause also executes if any break, continue, or return statement causes the try block to be exited.

The finally clause can be combined with exception handlers, provided that the finally clause comes last. The following program attempts to read integers from a file. The finally clause is always executed, even if some exception occurs when reading the data (such as if the file contains letters, thus causing int() to raise an exception, or if the file does not exist).

Figure 12.5.1: Clean-up actions using finally.

```
nums = []
rd_nums = -1
my_file = input('Enter file name: ')

try:
    print('Opening', my_file)
    rd_nums = open(my_file, 'r')  # Might cause
IOError

    for line in rd_nums:
        nums.append(int(line))  # Might cause
ValueError
except IOError:
    print('Could not find', my_file)
except ValueError:
    print('Could not read number from', my_file)
finally:
    print('Closing', my_file)
    if rd_nums != -1:
        rd_nums.close()
    print('Numbers found:', ' '.join([str(n) for n in
nums]))
```

```
Enter file name: myfile.txt
Opening myfile.txt
Closing myfile.txt
Numbers found: 5 423 234
...
Enter file name: myfile.txt
Opening myfile.txt
Could not read number from
myfile.txt
Closing myfile.txt
Numbers found:
...
Enter file name: invalidfile.txt
Opening invalidfile.txt
Could not find invalidfile.txt
Closing invalidfile.txt
Numbers found:
```

PARTICIPATION ACTIVITY 12.5.2: Finally.

Assume that the following function has been defined.

```
def divide(a, b):
    z = -1
    try:
        z = a / b
    except ZeroDivisionError:
        print('Cannot divide by zero')
    finally:
        print('Result is', z)
```

1) What is the output of divide(4, 2)?

- Cannot divide by zero.
  Result is -1.
- Cannot divide by zero.
  Result is 2.0.
- Result is 2.0.

2) What is the output of divide(4, 0)?

- Cannot divide by zero.
  Result is -1.

- Cannot divide by zero.
  Result is 2.0.
- Result is 0.0.

12.6 Custom exception types

When raising an exception, a programmer can use the existing built-in exception types. For example, if an exception should be raised when the value of my_num is less than 0, the programmer might use a ValueError, as in `raise ValueError("my_num < 0")`. Alternatively, a ***custom exception type*** can be defined and then raised. The following example shows how a custom exception type LessThanZeroError might be used.

Figure 12.6.1: Custom exception types.

```
# Define a custom exception type
class LessThanZeroError(Exception):
    def __init__(self, value):
        self.value = value

my_num = int(input('Enter number: '))

if my_num < 0:
    raise LessThanZeroError('my_num must be
greater than 0')
else:
    print('my_num:', my_num)
```

```
Enter number: -100
Traceback (most recent call last):
  File "test.py", line 11, in <module>
    raise LessThanZeroError('my_num must
be greater than 0')
__main__.LessThanZeroError
```

A programmer creates a custom exception type by creating a class that inherits from the built-in Exception class. The new class can contain a constructor, as shown above, that may accept an argument to be saved as an attribute. Alternatively, the class could have no constructor (and a "pass" statement might be used, since a class definition requires at least one statement). A custom exception class is typically kept bare, adding a minimal amount of functionality to keep track of information that an exception handler might need. Inheritance is discussed in detail elsewhere.

Good practice is to include "Error" at the end of a custom exception type's name, as in LessThanZeroError or MyError. Custom exception types are useful to track and handle the unique exceptions that might occur in a program's code. Many larger third-party and Python standard library modules use custom exception types.

PARTICIPATION ACTIVITY 12.6.1: Custom exception types.

1) A custom exception type is usually defined by inheriting from the Exception class.
   - True
   - False

2) The following statement defines a new type of exception: `def MyMultError: pass`
   - True
   - False

3) "FileNotOpen" is a good name for a custom exception class.
   - True
   - False

12.7 LAB: Fat-burning heart rate

Write a program that calculates an adult's fat-burning heart rate, which is 70% of the difference between 220 and the person's age respectively. Complete fat_burning_heart_rate() to calculate the fat burning heart rate.

The adult's age must be between the ages of 18 and 75 inclusive. If the age entered is not in this range, raise a ValueError exception in get_age() with the message "Invalid age." Handle the exception in __main__ and print the ValueError message along with "Could not calculate heart rate info."

Ex: If the input is:

```
35
```

the output is:

```
Fat burning heart rate for a 35 year-old: 129.5 bpm
```

If the input is:

```
17
```

the output is:

```
Invalid age.
Could not calculate heart rate info.
```

334598.939404.qx3zqy7

12.8 LAB: Exception handling to detect input string vs. integer

The given program reads a list of single-word first names and ages (ending with -1), and outputs that list with the age incremented. The program fails and throws an exception if the second input on a line is a string rather than an integer. At FIXME in the code, add try and except blocks to catch the ValueError exception and output 0 for the age.

Ex: If the input is:

```
Lee 18
Lua 21
Mary Beth 19
Stu 33
-1
```

then the output is:

```
Lee 19
Lua 22
Mary 0
Stu 34
```

12.9 LAB: Exceptions with lists

Given a list of 10 names, complete the program that outputs the name specified by the list index entered by the user. Use a try block to output the name and an except block to catch any IndexError. Output the message from the exception object if an IndexError is caught. Output the first element in the list if the invalid index is negative or the last element if the invalid index is positive.

Note: Python allows using a negative index to access a list, as long as the magnitude of the index is smaller than the size of the list.

Ex: If the input of the program is:

```
5
```

the program outputs:

```
Name: Jane
```

Ex: If the input of the program is:

```
12
```

the program outputs:

```
Exception! list index out of range
The closest name is: Johnny
```

Ex: If the input of the program is:

```
-2
```

the program outputs:

```
Name: Tyrese
```

Ex: If the input of the program is:

```
-15
```

the program outputs:

```
Exception! list index out of range
The closest name is: Ryley
```

12.10 LAB: Student info not found - custom exception types

Given a main program that searches for the ID or the name of a student from a dictionary, complete the find_ID() and the find_name() functions that return the corresponding information of a student. Then, insert a try/except statement in main() to catch any exceptions thrown by find_ID() or find_name(), and output the exception message. Each entry of the dictionary contains the name (key) and the ID (value) of a student.

Function find_ID() takes two parameters, a student's name and a dictionary. Function find_ID() returns the ID associated with the student's name if the name is in the dictionary. Otherwise, the function throws a custom exception type, StudentInfoError, with the message "Student ID not found for *studentName*", where *studentName* is the name of the student.

Function find_name() takes two parameters, a student's ID and a dictionary. Function find_name() returns the name associated with the student's ID if the ID is in the dictionary. Otherwise, the function throws a custom exception type, StudentInfoError, with the message "Student name not found for *studentID*", where *studentID* is the ID of the student.

The main program takes two inputs from a user: a user choice of finding the ID or the name of a student (int), and the ID or the name of a student (string). If the user choice is 0, find_ID() is invoked with the student's name as one of the arguments. If the user choice is 1, find_name() is invoked with the student's ID as one of the arguments. The main program finally outputs the result of the search or a message if an exception is caught.

Note: StudentInfoError is defined in the program as a custom exception type. StudentInfoError has an attribute to store an exception message.

Ex: If the input of the program is:

```
0
Reagan
```

and the contents of dictionary are:

```
'Reagan' : 'rebradshaw835',
'Ryley' : 'rbarber894',
'Peyton' : 'pstott885',
'Tyrese' : 'tmayo945',
'Caius' : 'ccharlton329'
```

the output of the program is:

```
rebradshaw835
```

Ex: If the input of the program is:

```
0
Mcauley
```

the program outputs an exception message:

```
Student ID not found for Mcauley
```

Ex: If the input of the program is:

```
1
rebradshaw835
```

the output of the program is:

```
Reagan
```

Ex: If the input of the program is:

```
1
mpreston272
```

the program outputs an exception message:

```
Student name not found for mpreston272
```
